## Abstract

SignWriting is a system for transcribing sign languages, using iconic depictions of the hands and other body parts, as well as exploiting the possibilities of the page as a two dimensional medium to capture the three-dimensional nature of signs. This goes beyond the usual line-oriented nature of oral writing systems, and thus requires a different approach to its processing. In this article we present a corpus of handwritten SignWriting, a collection of images which transcribe signs from Spanish Sign Language. We explain the annotation schema we have devised, and the decisions which have been necessary to deal with the challenges that both sign language and SignWriting present. These challenges include the transformational nature of symbols in SignWriting, which can rotate and otherwise transform to convey meaning, as well as how to properly codify location, a fundamental part of SignWriting which is completely different to oral writing systems. The data in the corpus is fully annotated, and can serve as a tool for computational training and evaluation of algorithms, as well as provide a window into the nature of SignWriting and the distribution of its features across a real vocabulary. The corpus is freely available online at <https://zenodo.org/record/6337885>.

## Acknowledgments

The VisSE corpus was created thanks to funding from the project “Visualizando la SignoEscritura” (VisSE, Visualizing SignWriting<sup>1</sup>), reference number PR2014\_19/01, funded by Indra and Fundación Universia, and development continues thanks to the project “SSL Signary: A parametric dictionary of Spanish Sign Language”<sup>2</sup>, reference number IN[21].HMS\_LIN\_0070, supported by a 2021 Leonardo Grant for Researchers and Cultural Creators from the BBVA Foundation. The BBVA Foundation accepts no responsibility for the opinions, statements and contents included in the project and/or the results thereof, which are entirely the responsibility of the authors.

## 1 Introduction

Modern linguistics rely ever increasingly on digital data, source instances of language along with annotations of their origin, meaning, or features. These assets are often organized into datasets or corpora, collections of annotated linguistic data sharing a theme or object of study. The creation and sharing of datasets can help immensely in the research of a certain subject, allowing empirical investigation as well as providing a shared substrate on which to discuss and compare theories.

As an object of increasing linguistic scrutiny, sign languages have also seen the construction of diverse corpora in recent times, covering some of the more than a hundred different sign languages in use in the world. Sign languages, however, present unique challenges due to their viso-gestual nature and, especially for linguists, their lack of a standard and widespread form of writing.

Often, sign languages are recorded using video, and the meaning annotated using glosses from the oral language in the same geographic region. This is, however, not a proper transcription, since sign languages are natural languages

<sup>1</sup><https://www.ucm.es/visse>

<sup>2</sup><https://www.ucm.es/signariolse>

with a grammar and lexicon of their own, and to properly capture them a “native” system is needed.

There are a few existing proposals for transcribing sign languages into a written form. Unique among them, SignWriting transposes the three-dimensional nature of signs into a bi-dimensional arrangement of symbols, as can be seen in Figure 1. Different iconic symbols are used to represent the head, hands and other body parts, and their location and movement is recorded in an abstract and systematic manner.

However, the graphical nature of SignWriting means it is very different from the usual writing systems for oral languages, making it harder to process with existing tools and standards. Moreover, while there exist some computational representations, very often SignWriting is shared in the form of images, which do not require special fonts and software installed to be viewed, but are impossible to process as text.

Therefore, to be able to linguistically process SignWriting in its image form, tools and standards are required. If these are to be developed empirically, source data is also needed. A few collections of sign language transcribed using SignWriting exist, but are not research oriented and deal only with the digital representation. Additionally, SignWriting can also be handwritten, and there are no research corpora of handwritten SignWriting that we are aware of.

In this article, we present the VisSE corpus of Spanish SignWriting, a collection of handwritten SignWriting instances representing signs of Spanish Sign language. The instances have been graphically annotated, for which an extensive schema has been developed, recording both the lexical meaning of the different symbols involved as well as their spatial information, a fundamental part of SignWriting.

This corpus can be used to extract information on SignWriting, for research on the processing of graphical languages, for empirical study of the features of sign languages, for the training and evaluation of machine learning methods, or for other research purposes which have not occurred to us. We have used it in our previous and ongoing research, and therefore, believing it may be of use to the research community at large, we have freely released it online (Sevilla, Lahoz-Bengoechea, & Díaz Esteban, 2022). We will continue to expand and improve it, and this article relates its current state, how it has been built and the annotation schema used.

In section 2, related corpora and tools are discussed, as well as systems for computationally storing SignWriting. Section 3 explains the different objects in the corpus and how have they been annotated, while section 4 is centered on the concrete details and computational aspects of its construction. Section 5 gives an overview of the data and some statistics, and in section 6 a few conclusions are drawn and future work described.

Due to its complexity, explaining SignWriting is out of the scope of this article, but enough detail will be given to allow the reader to follow the discussion. For more information, interested readers can see the extensive documentation available online at <https://signwriting.org>.

## 2 Related Work

Existing sign language corpora or datasets are usually comprised of videos of utterances, whether isolated signs or phrases. Many are not intended for research, but rather for user consumption, and are structured as dictionaries.

Spread the Sign<sup>3</sup> (Hilzensauer & Krammer, 2015) and DILSE<sup>4</sup> (Moreno, 2012) are two of these dictionaries containing the Sign Language translations (as video) of words in one or many oral languages. These videos are provided as-is, without any phonetic annotation, though DILSE is interesting in that, additionally to the video, it includes static photographs of signers where movement is annotated using superposed arrows, and when needed, different instants of the sign are recorded as consecutive photographs. We see this as an approach halfway to SignWriting, which follows similar principles but in a more abstract and standardized manner.

Other datasets, even if often also intended to be usable as dictionaries, are structured to allow research by examining the data or searching by features instead of just by meaning. LSE-Sign (Gutierrez-Sigut, Costello, Baus, & Carreiras, 2016) is a web tool that contains 2400 signs from Spanish Sign Language, annotated with linguistic features to enable searching for concrete characteristics of signs. The signs are stored as videos and glosses, but the annotation is rich, with entries for hand shape and orientation, movement shape, and other features. Other such corpora of sign language videos exist, such as those for Australian Sign Language, British Sign Language, and others, based on the Signbank software (Cassidy et al., 2018).

A common necessity of sign language corpora is a relevant and meaningful annotation of the signs depicted, since video by itself is not computationally processable. To this end, phonological or phonetic transcriptions of signs can be used, but there is not a universally accepted way to represent the movements and gestures of sign language neither formally nor computationally. The forefather of sign language linguistics, William Stokoe, proposed a linear writing system consisting of abstract symbols to encode the different parameters of the language (Stokoe, 1960). The Hamburg Notation System (Hanke, 2004) uses a similar approach but with a different set of symbols, while Ángel Herrero Blanco, in his study of Spanish Sign Language, developed another featured writing system but using characters from the roman alphabet (Herrero Blanco, 2003).

A different approach to sign language transcription can be found in SignWriting (Sutton & Frost, 2008), a featural writing system (Galea, 2014, pp. 76-77) where abstract symbols are used for representing linguistic features. Their shape is chosen as iconic as possible, helping the reader and writer remember the actual physical articulator the symbol represents. The main difference that SignWriting introduces is that symbols are also arranged iconically, instead of in a linear fashion. The bi-dimensional page is used to represent three-dimensional sign space, and symbols are set on it according to

---

<sup>3</sup><https://www.spreadthesign.com>

<sup>4</sup><https://fundacioncnse-dilse.org>

their actual location in the realization of the sign. This enables the writer to capture the spatial richness of sign language directly, but is a radical departure from the main paradigm of oral writing systems.

One of the problems this presents is that the common computational representation of oral writing systems, as sequences of individual and mostly independent symbols, is insufficient for representing SignWriting. Nonetheless, there is ongoing effort to solve this problem, and some of SignWriting can be represented using Unicode.

Unicode is a “universal character encoding standard for written characters and text” ([The Unicode Consortium, 2021](#)) which assigns a number to each possible character in use in a documented human language, so that text can be computationally stored as a sequence of bytes. It includes character points and combinations for many of the symbols in SignWriting, and [The International SignWriting Alphabet \(Sutton & Slevinski, 2010\)](#) provides fonts which, when installed in the user’s computer, allow for the proper display of the symbols.

However, “the spatial arrangement of the symbols (...) constitutes a higher-level protocol beyond the scope of the Unicode Standard” ([The Unicode Consortium, 2021](#), p. 831), meaning Unicode is not enough to fully codify SignWriting. To solve this problem, computational solutions often store positional information as numerical coordinates alongside the Unicode bytes, indicating where to place them in bi-dimensional symbol space ([Slevinski, 2016](#)).

Compared to video-based corpora of sign language, there are not many databases of sign language which use SignWriting as their representation form. SignPuddle<sup>5</sup> is a dictionary and database of sign language which stores SignWriting using Unicode and storing symbol positions as coordinate pairs. It is a multilingual dictionary, containing entries for many different sign languages across the world, including Spanish Sign Language. The web interface allows searching by word, symbol or searching full signs, and data can be exported for offline processing.

### 3 Annotation Schema

The VisSE corpus is a collection of handwritten SignWriting instances (images) representing signs or parts of signs from Spanish Sign Language. These instances are annotated both graphically, by demarcating the relevant regions of the image where meaning is codified, and more conventionally using textual tags to codify the meaning and attributes of the different symbols.

#### 3.1 Logograms

We call each of the SignWriting instances a “logogram”, since they represent units of meaning which are often words, but sometimes parts of them<sup>6</sup>. Unlike in actual logographic writing systems, however, the meaning of logograms is

---

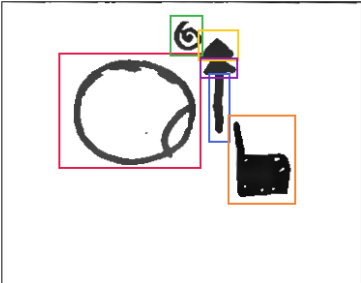

<sup>5</sup><https://www.signbank.org/signpuddle2.0/>

<sup>6</sup>Whether these are syllables, morphemes, or maybe something else is a question of linguistic research.

**Fig. 2:** Visual annotation of the sign “lie/to lie”. Superposed over the logogram image, the bounding boxes of the different graphemes are drawn. The color codes serve to match each region to their grapheme, represented to the right as a table of feature names and values.

purely phonetical, transcribing not the semantic meaning of the sign but rather the phonetic gestures necessary to articulate it. These gestures (understood in the broad articulatory sense) are codified in smaller symbols, units of writing that we call “graphemes”.

Graphemes codify most of the phonetic content of SignWriting, and so they require the most complex annotation, consisting of not a single label but a set of features for each grapheme. The list of graphemes present, along with their feature set, is the core of each logogram’s annotation.

However, the meaning of each grapheme is not only determined by its graphical properties, but also by its position relative to the other graphemes in the logogram. It is only after contemplating both each grapheme’s features and their holistic arrangement in the page that can the sign transcribed by a logogram be understood.

Therefore, logogram annotation consists of a list of graphemes with their relative locations, each annotated with their own independent feature set. The locations are annotated as ‘bounding boxes’, the geometrical regions within the logogram where each of the graphemes can be found. An example of this logogram annotation can be seen in Figure 2.

## 3.2 Graphemes

Unlike other writing systems, graphemes in SignWriting are not a one-to-one mapping from a shape or picture to a phoneme or phonemic feature, but rather encode complex meaning in their graphic form and visual properties. They have internal structure, both in their graphical properties (strokes, fill) and in their presentation (rotation, reflection). Each of these properties are encoded in a set of tags, a mapping from feature names to feature values that stores their independent meaning.

Some of this meaning is “lexical”, in that the shape of the grapheme must be looked up in a dictionary to understand what it represents. This is mostly the shape and outline of the grapheme’s form, which while often iconic and thus intuitive for humans to remember, is in the end conventional and abstract. The rest of the grapheme’s meaning is “morphological”, in that it is derived from the graphical transformation of the grapheme’s form. For example, the grapheme may be filled with different patterns of black and white, or drawn rotated around its center.

To properly annotate this meaning, a schema of five different features or tags is used. The first two, the ‘CLASS’ and ‘SHAPE’, codify the lexical part of the grapheme’s meaning, while the rest, namely ‘VAR’, ‘ROT’ and ‘REF’, encode the graphical transformations. As we will see, not all graphemes can be transformed in the same way or at all, so not all graphemes use the same set of features. Which features need to be used is determined by the first tag, the ‘CLASS’, which separates graphemes into different groups according to their visual characteristics (mostly size and variability) as well as their transformation possibilities. We have settled in six classes for our corpus: ‘HEAD’, ‘DIAC’, ‘HAND’, ‘ARRO’, ‘STEM’ and ‘ARC’.

Once the ‘CLASS’ is determined, the ‘SHAPE’ completes the lexical meaning by refining the classification down to what a user of SignWriting might actually identify as a ‘character’. For example, a concrete hand shape, a symbol for a head or a contact mark. The rationale for the grouping and annotation of the different classes, as well as any further tags needed for any of them, are covered in the following.

‘HEAD’ and ‘DIAC’ have the simplest annotation, so are explained together in 3.2.1, while ‘HAND’ graphemes are the most complex and section 3.2.2 is fully dedicated to them. ‘ARRO’, ‘STEM’ and ‘ARC’ are grapheme classes used to annotate the significant components of movement markers, and so are described together in section 3.2.3.

### 3.2.1 Invariant graphemes

Two first classes of graphemes are ‘HEAD’ and ‘DIAC’. These groups of graphemes do not transform, so are always presented with the same picture, and the ‘SHAPE’ feature is enough to discern their independent meaning. They are separated into two classes mostly due to their graphical characteristics. ‘HEAD’ graphemes are big and sparse, while ‘DIAC’ graphemes are small and

**Fig. 3:** Three HEAD graphemes, representing different parts of the head as place of articulation. The first is SHAPE=chin; the second SHAPE=mouth, and the third SHAPE=smile. This third grapheme represents not only the head as a body part, but also the “smiling” facial expression, which can be semantically relevant in sign languages.

**Fig. 4:** In 4a, some DIAC graphemes from the corpus are shown. Clockwise from top left, the SHAPES are: wobble, flex\_hook, touch and brush. In 4b, the logogram for the sign ‘left-handed’ is shown. The touch grapheme marks that the hand should be in contact with the head, while the top two flex\_hook graphemes specify that the little finger must bend twice in the “hooking” manner (they are above a HAND grapheme, explained in the following).

compact. Nonetheless, they also have different characteristics in how they contribute to the meaning of a logogram.

‘HEAD’ graphemes, by depicting the head or some of its parts (eyes, nose, etc), establish a place of articulation, and the location of other graphemes is decided relative to them. Additionally, iconic representations of the eyes, mouth, and other elements can be used to transcribe facial expressions, an important non-manual parameter of sign languages. Some examples of ‘HEAD’ graphemes can be seen in Figure 3.

‘DIAC’ graphemes act more like diacritics, modifying the meaning of nearby graphemes in some predictable way—hence the name, though no profound thinking has been given to whether they actually count as traditional diacritics. Some examples of ‘DIAC’ graphemes are dynamic marks, which establish the coordination of the hands, or the velocity of the signing, thus affecting the whole logogram and having a mostly arbitrary place within it. Other marks, such as internal movements of the hand, or contact markers, must be placed nearby the graphemes which they modify, though there are no hard rules as to where exactly.

**Table 1:** Some SignWriting hand grapheme samples from the corpus along with the hand shape they represent.

In Figure 4 some example ‘DIAC’ samples can be seen, and their use in combination with other graphemes in the logogram.

### 3.2.2 Hand graphemes

Hands are the most prominent articulators of Sign Language, and have many degrees of freedom and articulatory possibilities. Different authors assign different features to signs, but some commonalities can be found. The “hand shape” or configuration is a feature that accounts for the articulatory possibilities of the fingers, i.e. how are they bent to produce a unitary and meaningful shape; orientation is a feature specifying the rotation of the hands as 3D objects in sign space.

In SignWriting, each different hand shape is assigned a “picture”, a combination of strokes that iconically represents the hand and the fingers. This basic picture can have different filling patterns of black and white, and can also be rotated or reflected. These different attributes are annotated separately in our corpus, to represent their combinatory possibilities. Hands are grouped under the `CLASS=HAND`, and present the most complex annotation, requiring all the features available in the corpus for their annotation.

The outline of the character, which SignWriting uses to represent the hand shape, is annotated in the tag ‘SHAPE’. This roughly corresponds to the sign language parameter of hand configuration, and therefore a suitable linguistic notation system can be used to transcribe it. Some different notation systems exist for hand shapes, varying in their applicability to different sign languages and their ease of use. We use our own notation system, somewhat similar to that of [Eccarius and Brentari \(2008\)](#), but specific for Spanish Sign Language. Some examples of hand shapes can be seen in table 1.

These basic “forms” for hand graphemes can suffer a number of graphical alterations in SignWriting, used to transcribe the hand as a three dimensional object in the flat page. The hand grapheme can be filled with three different patterns: full white, full black or half and half. Then, the grapheme can be rotated using a set of eight possible different angles. These two transformations encode the orientation of the hand, and are annotated in our corpus in the ‘VAR’ and ‘ROT’ features.

|     |   |   |   |   |   |   |
|-----|---|---|---|---|---|---|
|     |  |  |  |  |  |  |
| VAR | white   | white   | white   | half  | half  | black   |
| ROT | North   | South   | NorthEast   | North   | North   | North   |
| REF | no  | no  | yes   | no  | yes   | yes   |

**Table 2:** Hand graphemes and their transformational annotation. The label values have been expanded from the actual abbreviations used in the corpus to be more informative.

A final graphical transformation allows the hand graphemes to be reflected across their longitudinal axis, turning them into their mirror image. This transformation is used by SignWriting to better iconically depict the hand as would be seen by the signer, representing the fingers in their correct position across the hand and also being useful to represent left hands (which are mirror images of the right hand). This reflection is coded in our corpus in the ‘REF’ feature, using a *yes/no* value.

To decide whether a hand grapheme is reflected or not, however, is not as straightforward as it may seem. Without the wider context, it is impossible to predict whether a grapheme is an unreflected left hand or a reflected right one. For example, in table 2, the fourth grapheme could be either a right or a left hand, we only know that the palm is looking left. Conversely, the fifth grapheme does not tell us, without wider context, whether it is a left or right hand, but only that the palm is oriented to the right.

We choose to optimize graphical stability, meaning graphemes which are similar in features should also be similar graphically. To this effect we choose the ‘half’ variant as the guide for whether graphemes are reflected or not (choosing as non-reflected the one with the palm to the left), and base the ‘REF’ feature for white or black variants on their graphical similarity to the half one.

More examples of hand grapheme alterations can also be seen in table 2. For the complete enumeration and explanation of tag values, please refer to the annotation guide that can be found in the corpus (in English and Spanish, available inside the corpus distribution file or directly at <https://zenodo.org/record/6337885>).

### 3.2.3 Movement marks

Hand movements are an integral part of sign language, and therefore a substantial part of SignWriting. They are codified with paths and arrows depicting the 3D movements of the hands in the page, describing the shape of the movement by literally drawing it. To properly encode 3D space in 2D writing, they use graphical attributes to distinguish between planes of movement, similar to how ‘HAND’ graphemes have variations to represent different palm orientations. Some examples of movements in the corpus can be seen in Figure 5.

**Fig. 5:** Some logograms in the corpus which include movements of the hand. In 5a (“fingerspelling”), the hand moves to the right while the fingers “wiggle” (a ‘DIAC’). In 5b (“happy”), the hands simultaneously do parallel zigzagging downward movements. In 5c (“together”), the hands move from the sides to the center until they touch. Finally, in 5d (“Sign Language”), the hands make repeated circular movements in the vertical plane.

What constitutes a grapheme in movement markers, however, is not an easy decision. As with other elements of SignWriting, movement symbols use both symbolic graphical properties (strokes, filling, shapes) as well as location in the page to record information. The shape of sign language movement is directly and iconically converted into bi-dimensional trajectories, with a few graphical attributes to bridge the gap to the extra dimension.

One approach would be to understand the full trajectory and associated symbols of the movement as a unit. This is the approach used by the Unicode standard and the International SignWriting Alphabet, even if some of the features, such as rotation, are encoded as different codepoints forming combining characters. Indeed, there are tens of thousands of glyphs in the International SignWriting Alphabet fonts to try and account for as many possible movements as possible, a small sample of which can be seen in Figure 6. Encoding movements holistically is, however, problematic for annotation due to the sheer number of them, and there is arguably a loss of information incurred when transforming a visual, meaningful, spatial representation into an index in a table. Additionally, dealing with handwritten SignWriting renders this

**Fig. 6:** Small sample of characters that can be found in the Sutton SignWriting fonts to represent different movements of the hand.

approach even more difficult, since it is not guaranteed that transcriptions will use only the abstractions that are collected in the Unicode representation.

Instead, we have opted to characterize the different elements of movement markers as individual graphemes. From the “lexical” annotation point of view, this makes sense because there are repeated elements, with identifiable semantics of their own, which can be used in different context. While these elements could be transcribed as different tags for the same grapheme, as is done for hands, their independent spatial characteristics make a subdividing approach more useful.

In Figure 6 we can see that arrow heads are repeating elements, as well as straight path segments, arcs and circles. Since each of them has a distinctive meaning (black arrow heads represent right hand movements, white ones left hand movements, double stemmed movements occur in the vertical plane, etc.) and there are movement marks which are distinguished only by the presence or absence of one of them, it is reasonable to think of each independent segment as individual graphemes.

Therefore, we have settled on three different classes of movement graphemes: arrow heads ‘ARRO’, straight segments ‘STEM’ and curved segments ‘ARC’. The ‘SHAPE’ tag for each of them distinguishes between the few different variants in the CLASS: in the case of ‘ARRO’, the color of the arrow head marks which hands move, and is encoded in the ‘SHAPE’. ‘STEM’ and ‘ARC’ can occur in different planes of movement, distinguished by their stems, so this is annotated in the ‘SHAPE’. For ARCs, the ‘SHAPE’ additionally stores the amplitude of the movement, since curved movements can be shorter or longer arcs or even full circumferences.

Additionally to the ‘SHAPE’, all movement graphemes can be rotated to convey orientation in 3D space. This is annotated in the ‘ROT’ tag, as is done for hands, and following the same notation using cardinal directions<sup>7</sup>. The ‘REF’ tag is not needed thanks to subdividing movements into segments, since each individual segment is symmetric. If movement markers were annotated as a whole, annotating reflection would be necessary for ‘ARC’s to distinguish clockwise and anti-clockwise orientations, but with our approach it is not necessary (it is marked by the position of the arrow head).

<sup>7</sup>For the specific details please see the annotation guide of the corpus.

**Fig. 7:** Annotation of sub-segment bounding boxes for movement and forearm markers in some logograms from the corpus. The signs are “happy” in 7a, “bridge” in 7b, “Zaragoza” in 7c and “November” in 7d.

Some examples of this path subdivision can be seen in Figure 7.

The subdivision approach also helps with marking the bounding boxes for movement graphemes. Movement paths are very graphically “sparse”, the actual strokes often occupying a small part of the whole rectangular region they occupy. The bounding box of the full path is not very informative either, not being able to distinguish the actual shape of the paths or their direction. This could be annotated a posteriori, but it seems a waste of effort to try to reconstruct a geometric meaning by abstract terms when the description is there, on the page, using geometric features which we can spatially annotate.

Another instance where the segmenting approach helps is with crossings and overlapping graphemes. It is very common for movement markers to overlap each other. Sometimes this is not a problem, for example a small ARC crossing over a long STEM, as is done to indicate forearm rotation. Their geometric properties are distinct enough that spatial annotation can be reasonably performed, their bounding boxes in a distinguishable and characteristic arrangement even if there is much overlap (see Figure 7b). However, when there is a diagonal crossing of STEMs, as in Figure 7d, the bounding boxes overlap so much that they become meaningless. In this case, the paths are

subdivided into consecutive sub-segments, forming a meaningful arrangement of movement graphemes which can be annotated and processed.

Despite the advantages we have explained, subdividing the movement markers present one small problem. With this schema, some markers used in SignWriting to represent body parts like shoulders, the waistline, or forearms become indistinguishable to STEMs. Indeed, in the case of forearms, this similarity is not a coincidence, since they have the same features and behaviours of movement paths. They can be double or single, depending whether the forearm is vertical or horizontal, and they can have overlapping ARCs to represent forearm rotation. The only difference is that these “STEM”s are not topped by an arrow head. Fortunately, this is also the solution to our problem. Shoulders, forearms etc. are annotated as STEMs, and their actual meaning is contextual, depending on the presence or absence of actual ARRO graphemes in their extremes. While this pushes interpretation of graphemes’ meaning to a further layer of processing which can take context into account, this is already a feature of SignWriting and our annotation, so this decision maintains coherence and makes the corpus consistent.

## 4 Corpus Construction

The VisSE corpus was built as part of the equally named VisSE project<sup>8</sup> (“Visualizando la SignoEscritura”, “Visualizing SignWriting” in Spanish) which had the goal of improving the use and access of SignWriting in digital contexts. To form the base for further study as well as training samples for machine learning development, around 1950 instances of raw SignWriting were collected. These samples had been collected by Dr. José María Lahoz-Bengoechea during a span of years while learning Spanish Sign Language at Universidad Complutense de Madrid, and were originally a tool for his private study.

The samples were handwritten with pen or pencil, and collected in vocabulary sheets. As part of the project, they were digitized, separated into different files for each entry, and graphically enhanced to reduce scanning artifacts and other noise. During this process, a reference to the original vocabulary entry was kept, and remains as a tentative “gloss” (in Spanish) for logograms in the corpus.

The logograms are collected in subsets according to the academic level at which they were collected. This has no further intended meaning than being a way to organize the corpus, but it results in some greater graphical and usage consistency within each of the subsets. This has let us do annotation incrementally, learning from each phase and improving the annotation schema each time a new set was added. In the current release of the corpus, not all of the original logograms are present, but only those which have been annotated and revised. These are sets A1\_1, A1\_2, A1\_3, A2 and B2\_2, which include 1146 annotations.

---

<sup>8</sup><https://www.ucm.es/visse>

Apart from learning from the annotation process and improving it for the following subset, this incremental approach allowed us to use a bootstrapping approach to annotation. Once the first set had been fully manually annotated, machine learning algorithms were trained on it and used to perform a preliminary annotation of the next subset. The resulting annotations had to be checked and corrected manually, but the process was somewhat faster. Some graphemes are easy to detect for the machine learning algorithms, meaning the human annotators could focus on the more difficult parts. As the algorithms improved, the speedup was evident, and some of the tasks could be somewhat automatized, like the drawing of bounding boxes for each grapheme. Readers interested in the machine learning aspect of our research can find more information in our forthcoming article “Automatic SignWriting Recognition”.

## 4.1 Quevedo

The process of collecting, organizing, annotating, and performing machine learning on the data was a complex one, compounded by the fact that we were developing the annotation schema in parallel to the actual annotation of the data. Moreover, our annotations are complex and very specific, including both visual annotation of logograms and a multi-feature annotation of graphemes. To deal with this complexity and the specific requirements of our task, a specialized tool was developed as part of the VisSE project, named Quevedo<sup>9</sup>. Therefore, computational access to the corpus and its features is easiest when using Quevedo, and the on-disk format and organization of the corpus is as a Quevedo dataset.

Quevedo is available on the Python Package Index, so installing it can be done with the command `python3 -m pip install quevedo[web]` if Python and Pip are available. This will also install the web interface, which can be launched with `quevedo web` at the corpus root directory, allowing visual inspection of the logograms and their annotation.

The features of Quevedo and the format on disk are all explained in the online documentation, but are also briefly detailed in the following for parties who want to use the corpus with other tools or need access to the low-level details. All formats are open and standard, so all the data and features in the corpus can be thus accessed.

## 4.2 Computational representation and access

Logograms in the corpus are stored in the `logograms` directory, in subdirectories representing each of the subsets. Files are sequentially numbered, starting from 1, and each instance consists of two files. The source image is named with the index of the annotation plus file extension `.png`, and the annotation

---

<sup>9</sup> Available at <https://github.com/agarsev/quevedo>. An article detailing its features and internal working can be found in Sevilla, Díaz Esteban, and Lahoz-Bengochea (2022).

data uses the same filename (the index) but with `.json` extension. For example, the annotation data corresponding to image `logograms/A1.1/1.png` can be found in the file `logograms/A1.1/1.json`.

The json annotation file is a dictionary of attributes, among which there is a `graphemes` key containing an array of the different graphemes found in the logogram. Each of them is a dictionary as well, having a `box` key with the coordinates of the bounding box, and a `tags` key which is another dictionary representing the mapping from feature names to feature values.

The coordinates of the bounding boxes are 4-tuples of floating point numbers, in the format  $(cx, cy, w, h)$ .  $(cx, cy)$  are the coordinates of the center of the box relative to the logogram, which range from 0 to 1,  $(0, 0)$  being the top left corner, and  $(1, 1)$  the bottom right one.  $(w, h)$  are the width and height of the grapheme region, again relative to the width and height of the logogram, so ranging from 0 to 1. The grapheme tags are stored as strings of characters both for feature names and value.

Aside from the `graphemes` key, logogram annotation files include some other information used by Quevedo. The `meta` key stores a dictionary of additional metadata keys for the logogram, where the original gloss for the logogram can be found, as well as some boolean ‘`flags`’ which we have used to mark and exclude a few problematic graphemes.

There is also a `fold` key which stores a number, the index of the “fold” to which the annotation belongs. Folds can be used to split the data in the corpus along a different dimension from that of the subsets, which can be useful, for example, for logically partitioning the data into training and evaluation sets. Storing this split into the annotations as a “fold” number helps make experiments reproducible and sound and results comparable. Each logogram is assigned a number ranging from 0 to 9, and this numbers split the corpus data into 10 approximately equally-sized folds. In our experiments we use folds 0-7 for training, and 8-9 for testing.

An example annotation file can be seen in appendix [A](#).

### 4.3 Other files

Inside the corpus root directory there are a number of other files and directories not mentioned above. Especially relevant is the ‘`networks`’ directory, where the weights of neural networks trained with the corpus data are stored. These are included with the corpus so that interested parties can reproduce some of our experiments and pipelines without having to train the algorithms themselves. Visual testing of the networks and pipelines is also possible using the Quevedo web interface.

In the ‘`scripts`’ directory, some utility Python scripts are also included, and some researchers might find them useful. A ‘`dvc.yaml`’ file can also be found in the root directory, for use with DVC ([Kuprieiev et al., 2021](#)). This file can be used to run some common tasks with the data from the corpus. Relevant here may be the ‘`extract`’ step, which will extract all graphemes from the logograms and turn them into their own annotation files in a ‘`graphemes`’

| CLASS | Graphemes | Unique Observations | SHAPes | Appearance Rate |
|-------|-----------|---------------------|--------|-----------------|
| HAND  | 1649      | 560                 | 72     | 1.68            |
| ARRO  | 1369      | 23                  | 3      | 1.39            |
| STEM  | 1292      | 15                  | 2      | 1.32            |
| DIAC  | 1047      | 19                  | 19     | 1.07            |
| ARC   | 373       | 37                  | 6      | 0.38            |
| HEAD  | 330       | 20                  | 20     | 0.34            |
| total | 6060      | 674                 | 122    | 6.17            |

**Table 3:** Counts of observations in the corpus by CLASS. Unique observations refer to those which share the same set of features. The rate of occurrence is the number of observations divided by the total number of logograms, measuring how likely a grapheme class is to appear in a logogram.

directory, allowing them to be processed independently of the rest of the logogram.

For more information on the dataset structure or other files, please refer to Quevedo’s documentation at <https://agarsev.github.io/quevedo>, or to our other articles.

## 5 Data Description

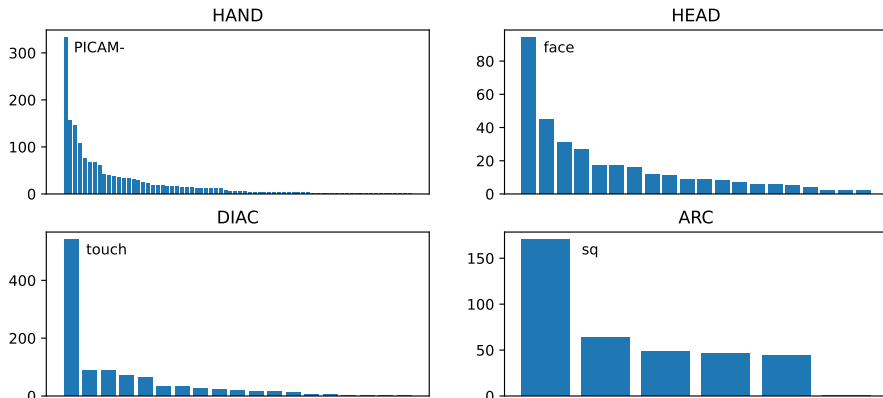

There are 1146 annotations in the corpus, 982 of which are fully annotated logograms. The rest of the annotations are marked using the ‘`exclude`’ flag, most of them being “long” transcriptions of polysyllabic signs rather than single logograms. These have been split into two (or more) independent logograms, but the original annotations are also included for reference. Some other transcriptions, marked with the flag ‘`problem`’, present some kind of graphical or representational problem, which has led us to exclude them for now from annotation, but are kept in the corpus.

Within the 982 fully annotated logograms, 6060 different graphemes can be found. Of these, 330 belong to the HEAD class, 1047 to DIAC, 1649 to HAND, 1369 to ARRO, 1292 to STEM and 373 to ARC. In table 3, these numbers can be compared to the number of different SHAPes that can be found for each CLASS. As can be seen, the proportions are very different, meaning that some classes, like ARRO or DIAC have only a few different possible grapheme SHAPes but are abundantly represented in the data, while other classes like HAND or ARC are less abundant compared to the variability within the class.

Examining the rate of appearance of grapheme classes per logogram, we can also make some interesting observations. The average amount of graphemes per logogram is about 6, 1.68 of which are hands. Unfortunately, we cannot distinguish between bimanual signs and transcriptions where a transformation in handshape is encoded, but further, “semantic” annotation would make this clear. Easier to compute is the “complexity” of movement paths. Since most movements are marked with an arrow head, the ratio of segments (STEM and ARC) to arrow heads (ARRO) can give us an approximate measure of the mean

**Fig. 8:** Distribution of unique tag combinations in the corpus. The most common 80 are arranged in the horizontal axis (not labeled for clarity), while the vertical axis represents the number of times that unique combination appears in the corpus. The bars are also color-coded by CLASS. The plot would extend to the right more than 6 times, making the “long tail” even longer and thinner.

**Fig. 9:** Distribution of shapes for some classes. The horizontal axis represents the shapes (not labeled for clarity), the vertical axis is the number of times that shape appears in the corpus. The most common CLASS is labeled near its bar for reference.

number of segments for paths:  $\frac{1292+373}{1369} \approx 1.22$ . This means that most movement markers are simple, with just one stem segment, but a non-trivial amount (approximately one every five) is more complex, having two or more segments.

If we examine the distribution of tag combinations, however, we can see a very skewed distribution, as is depicted in Figure 8. Some graphemes are very common, while many combinations are rare, forming a very “long tail” of infrequent graphemes. This also happens if we just look at the SHAPE feature, and across classes, as can be seen in Figure 9.

Since this is not a corpus of real utterances or texts, but rather a vocabulary, conclusions cannot be directly inferred about the frequency of elements in

SignWriting in use. However, we can make observations across the vocabulary of the transcribed sign language, seeing that some particular gestures (understood in the broad linguistic sense) are much more common than others. For example, the “touch” grapheme is extremely common, as well as the PICAM-hand shape (fingers extended but together, which acts as the “flat” object descriptor in Spanish Sign Language, the top left hand shape in Table 1).

## 6 Conclusion

SignWriting is a complex writing system used to transcribe sign languages. Its power as a faithful phonetic representation of signs, both in the lexical and the spatial domains, means it can be a useful tool for empirical linguistic research. For this to work, examples and empirical processing methodologies need to be developed and tested.

To this end, we have built the VisSE Corpus of Spanish SignWriting, a collection of handwritten SignWriting logograms which can be used for automatic processing or linguistic analysis of the data. The corpus is freely available online, and in this article we have presented its annotation schema and construction, and we have performed a brief analysis of the data it includes. We have seen that processing SignWriting requires careful analysis, and believe our work may be useful for the research community both in how we have proceeded as well as in the end result, the published corpus.

As an example of the insight that can be gained from having data and annotating it, we have observed in our research that, just as sign languages share some characteristics with oral ones, they are different in the use of space and movement. SignWriting shares some characteristics of oral writing systems, such as the presence of characters, but differs in its use of the spatial properties of the page to encode meaning.

Due to the complexity of sign languages at the phonetic level, SignWriting can be a powerful and flexible tool for dealing with them, thanks to its very detailed and phonetically precise nature. However, it requires a mental and computational model more complex than that of other writing systems. To deal with this complexity, we think it is useful to think of SignWriting as a language in itself, albeit a graphical one.

This mental model can be seen in our classification of graphemes in hierarchies (reminiscent of parts of speech), and their complex annotation using sets of features which somewhat resemble morphological features of words. In the corpus and in this article not much attention has been paid to these “semantic” properties of graphemes, since we have focused on their descriptive annotation. However, we want to note that this similarity of SignWriting elements to words in an oral language, with their syntactic and morphological properties, is not only found in their appearance, but also in their interpretation. Properly extracting this interpretation is a task which remains as future work.

On the other hand, just as space and movement are still unresolved issues for sign language theoretical description, annotation of spatial properties of

SignWriting graphemes has been a challenge where we could not base ourselves in any widespread linguistic standard or know-how. We have seen that some of the graphical attributes of graphemes are similar to morphological derivational processes, manifesting as rotations and reflections of characters rather than their insertion or deletion. But others, intrinsically locative, require numerical annotation of positions and regions, and subdivision of paths into smaller elements.

We believe this insight might not be only useful for the computational treatment of SignWriting, but may also mirror some of the problems of computational treatment of sign language per se, and may inspire solutions or ideas in that space.

Moreover, as SignWriting elements map very well to the phonetic features of sign languages, especially when annotated in detail like is done in the VisSE corpus, we think that the study of a corpus of SignWriting can very well be useful to draw conclusions about the sign language it transcribes. This can help make data-based linguistic research on sign languages less costly, as collection of video corpora requires much time, face-to-face collaboration of native informants, and attention to issues such as privacy and distribution of the videos. Linguistic annotation of video is difficult and essentially a manual process, while annotating SignWriting can be faster with the right tools, or can be even done with hand written samples as we show in this corpus, and using the machine learning algorithms trained on it.
